

A PROTEOGENOMICS FRAMEWORK FOR DISCOVERY OF TRANSLATED
MICROPEPTIDES IN MOUSE BRAIN AND OTHER SYSTEMS

Abstract

In this thesis, we developed methods for micropeptide discovery and applied these methods to several biological systems to find evidence of novel translated micropeptides. Micropeptides are small proteins translated from open reading frames shorter than 100 codons, and have historically been understudied in genome annotations. This framework allows discovery of these peptides, by an approach called proteogenomics, which combines mass spectrometry-based proteomics with deep sequencing-based transcriptomics in order to study the genome. We developed a bioinformatics framework for micropeptide discovery experiments, and also developed and validated an LC-MS/MS platform for micropeptide discovery. Finally, to show these methods are broadly applicable, we used these methods to analyze the liver proteome, the HIV-1 virion proteome, and the mouse cerebellum proteome, finding evidence of novel micropeptides in each case.

Micropeptides are thought to be low-abundance, and therefore difficult to detect by biochemical methods. A lack of sensitivity in proteomics is often due to suppression effects of high abundance molecules which co-elute with low abundance molecules. We developed a two dimensional chromatography platform, in which a strong cation exchange column is coupled in series with two hydrophobicity columns all coupled to a tandem mass spectrometer, allowing online fractionation of peptides. Applying this system to micropeptidomics, we have shown that sensitivity for micropeptides greatly increases as well. This system is applied in to discover novel micropeptides in human liver.

The framework was applied to several biological systems with varying degrees of genome complexity: the HepG2 liver cell line, to study the human liver proteome, purified HIV-1 virions, to study the packaged virion proteome, and the mouse brain. The three experiments represent a large range of genomic complexity: HIV-1 has a very small genome, the human genome is much larger, and the mammalian CNS genome is believed to be highly complex due to alternative splicing.

The human liver HepG2 cell line was subjected to proteogenomics analysis. A transcriptome assembly was translated *in silico* and used to search for peptide products from all possible open reading frames shorter than 100 codons. Two novel peptides were found with high confidence. Next, HIV-1 virions were subjected to proteogenomics. The HIV-1 genome is very small, so the whole genome was translated. In order to capture strain-specific differences, three biological replicates were genomically sequenced, and the resulting HIV-1 genome assemblies translated *in silico*. One novel peptide was observed in each replicate with high confidence.

Finally, the mouse brain was subjected to proteogenomics in order to find novel secreted peptides. The soluble fraction of mouse brain was used to generate proteomics data. As the mammalian CNS proteome is believed to be very complex due to alternative splicing we utilized ribosome profiling data, which allows reading frame and translation start sites to be determined. A translome was assembled from the frame determination and used to generate the database for proteomics analysis. Several micropeptides were again found, and in particular one highly expressed peptide was found to be enriched in behavior regulating regions of the brain.

Thus, applying the framework to several different biological systems shows that it is robust against various genomes so that micropeptides can be discovered in various experimental contexts. The results also suggest the ubiquity of micropeptide expression in all organisms.

Acknowledgements

If the reader will indulge me, I want here to thank some of the people who have helped me along the way to this thesis.

First, my mentor for the last two years, Akira Sawa, who has supported me tremendously and generously in my own intellectual development.

Second, the many other scientific mentors I have had along the way, including David Graham, Lennart Martens, Allen Everett, Gerhard Thallinger, Juergen Hartler, Alexey Lyashkov, Julia Drewes, Kelly Meulendyke, M. Christine Zink, Janice Clements, Lucio Gama, David Colquhoun, Shinichi Kano, Takahiro Kato, Graham Diering, Richard Haganir, Lindsay Hayes, Koko Ishizuka, Leslie Nucifora, Minae Niwa, Kyongman An, Rhoel Dinglasan, Julian Bess, Gerben Menschaert, and Robert Cole. Most importantly, I have to thank Dingyin Tao, Nicholas Ingolia and Rachel Green for their tireless support.

Finally, I have to thank my family, without whom this would never have been possible; my parents, Soma and George Tharakan, who made me believe this was possible, and my brothers, Raj and Anuj Tharakan. The debt I owe to Ceereena Ubaida-Mohien and Immanuel Tharakan is beyond words.

Some material presented in Chapter 2 has been previously printed in Journal of Proteome Research (Tharakan et al. 2015).

Chapter 1: Introduction

The sequencing and publication of complete genomic sequences of many organisms has aided the medical sciences greatly, allowing advances in both the genetics and biology of human disease and greater understanding of the biology of human pathogens. In particular, the human genome sequence has advanced human disease genetics by allowing genome-wide association studies (GWAS), and knowledge of gene sequences and their chromosomal loci has produced deeper understanding of the biology of all organisms whose genomes have been sequenced, including human pathogens such as HIV. Crucial to all of these efforts is genome annotation, which uses genomic, genetic, epigenetic, and other information to find loci in the genome which code functional genes. While genome annotation has been performed alongside efforts to sequence genomes, the continuing pace of novel gene discovery, aided by advancing technology in molecular biology and biochemistry, shows that annotation is often incomplete.

During the early stages of genome annotation, when genomes such as the human genome were first sequenced, a lower limit was placed upon the length of an open reading frame (ORF) that could be considered a possible gene (Bissette, Nemeroff, & MacKay, 1986; Dujon et al., 1994). These limits were set by modeling a biochemically equivalent random genome, and determining the ORF length distribution over that random genome, thus showing the length distribution of 'random' ORFs. In the case of the human genome, in order to exclude such random ORFs, the minimum ORF length was set to be 100 codons by reasoning about the size distribution of random ORFs. However, while a high proportion of ORFs below these limits may be spurious, there are also a substantial number which are real genes, and these are missed by such a filtering step (Basrai, Hieter, & Boeke, 1997). Furthermore, while gene discovery can be accomplished by means other than genome annotation, it appears that these original

genome annotation decisions continue to be reflected in our current understanding of genomes, since there is a disproportionately low number of genes annotated for the human genome below the 100 codon cutoff(Frith et al., 2006).

Recently, evidence has emerged that many of these short (<100 codons) open reading frames may indeed be protein-coding genes, whose gene products have been named 'micropeptides.' Evidence for functionality of these short peptides has come from several sources, including bioinformatics, through novel conservation analyses(Crowe, Wang, & Rothnagel, 2006), and biochemical approaches, such as expressed sequence tag experiments(Frith et al., 2006), deep sequencing based-experiments such RNA sequencing(Kageyama, Kondo, & Hashimoto, 2011) and ribosome profiling(Ingolia, Lareau, & Weissman, 2011). These micropeptides have been found in studies of many model organisms, suggesting that micropeptide genes indeed exist throughout all genomes. Nevertheless, it has been controversial how many micropeptide genes there are, and general estimates have varied by orders of magnitude. In particular, since all techniques have biases and false positives, there has been continued debate on the extent to which evidence for micropeptides is artifact of the techniques used for discovery(Guttman, Russell, Ingolia, Weissman, & Lander, 2013; Ingolia et al., 2014). Furthermore, the mechanisms by which micropeptides perform their functions in the cell is often difficult to define exactly; in particular, it is still not clear whether micropeptides as a class of protein share a general cellular role, or whether they have diverse functions in the same way large well-annotated proteins do.

In prokaryotes, annotation of short open reading frame (sORF)-encoded micropeptides has been of increasing interest. In the bacterium *Mycoplasma pneumoniae*, micropeptides translated from non-coding RNA (ncRNA) were discovered by mass spectrometry, defining the total complement of micropeptides in that organism's genome at 67, approximately 5% of all coding genes(Lluch-Senar et al., 2015). A

transposon-based essentiality screen found that 53% of these micropeptides were essential for the bacterium's growth, indicating that many micropeptides are not only functional but essential for bacterial growth. Since *M. pneumoniae* has a relatively small genome of 816 kb which is likely to be well annotated, such an essentiality study also suggests that many micropeptides are proteins essential for a minimal organism and thus essential for life(Lluch-Senar et al., 2015). Similarly, in the bacterial strains *Synechocystis* 6803 and *Synechocystis* 6714, and bioinformatics screen using BLAST searches found 293 transcriptional units putatively encoding micropeptides, of which 5 could be functionally characterized, showing structural features such as transmembrane helices and regulated expression during environmental perturbation and bacterial stress responses(Baumgartner, Kopf, Klahn, Steglich, & Hess, 2016; Hemm et al., 2010). Finally, in the widely used model bacterium *Escherichia coli*, 44 micropeptides have been found, many of which also perform basic functions in the cell(Hemm, Paul, Schneider, Storz, & Rudd, 2008).

Micropeptide discovery has also continued apace in eukaryotic model systems. A study in *Saccharomyces cerevisiae* by ribosome profiling found many cases of translation of micropeptides, which appear to serve some purpose during the meiotic process(Brar et al., 2012). During meiosis, translation of some 9,989 unannotated ORFs was found, with a mean lengths of the novel ORFs of 46.8 codons, much shorter than the average of known genes of 484.9, and substantially under the 80 to 100 codon cutoff which was used to annotate the yeast genome. These novel genes appeared to have their translation increased in a regulated fashion during meiosis, indicating once again that they are functional, although the functions of these many putative novel genes have not been defined yet(Brar et al., 2012). A bioinformatics screen of the yeast genome searching for micropeptides similarly yielded 184 yeast sORFs conserved across many species, suggesting that they may be functional(Kastenmayer et al., 2006). These novel

genes were then validated as to function by development of deletion strains for 140 of them, of which 9 gave clearly observable phenotypes. The latter study provides a model of how novel micropeptide genes can be validated as to function; furthermore, the large increase in the number of micropeptides observed between the two studies demonstrates the role of advancing technology in the rapid advance of micropeptide annotation.

Studies in higher-order animals have also found several significant novel micropeptides. Perhaps most relevantly for human health, a screen in *Danio rerio* discovered a novel micropeptide translated from a transcript annotated as a long non-coding transcript (lncRNA), christening the micropeptide *Toddler* (Pauli et al., 2014). This micropeptide was discovered by a series of screens, in which developing zebrafish were subjected to RNA sequencing to discover novel lncRNAs (Chew et al., 2013), and the same material was used for a ribosome profiling study (Pauli et al., 2012). The latter ribosome profiling study showed that 399 of the putative lncRNAs were indeed translated, of which one produced a micropeptide which was confirmed by mass spectrometry. GFP-tagging of the novel micropeptide to find tissue distribution and production of a knockout animal showed that the micropeptide appeared to function as an extracellular secreted ligand for the Apelin receptor, essential for cell migration during embryonic development (Pauli et al., 2014). Importantly, the same micropeptide was found to be essential for regulation of the human cardiovascular system, again functioning as a ligand for the Apelin receptor (Yang et al., 2017). As GPCRs are very frequently targeted by drugs, the discovery of this novel ligand could eventually produce a novel cardiovascular therapy, as has been recently proposed. This series of studies thus shows that discoveries of micropeptides in animals can not only be relevant for human biology, they can also almost immediately lead to novel therapies.

In another animal model system, *Drosophila melanogaster*, progress in annotation of micropeptides has been even more rapid. Several screens of this system have produced a number of novel micropeptides which regulate the cardiovascular system (Magny et al., 2013), developmental regulation through proteasomal function (Zanet et al., 2015), and control of RNA polymerase (Hanyu-Nakamura, Sonobe-Nojima, Tanigawa, Lasko, & Nakamura, 2008). In the cardiovascular system, the micropeptides Sarcolamban A and B were initially found in a search for functional sORFs among the set of putative ncRNAs, a screen which found two possible micropeptides of 28 and 29 amino acids long on a single transcript (Magny et al., 2013). *In vivo* translation and GFP tagging confirmed translation localized to the sarcoplasmic reticulum, and a null mutant showed a cardiac arrhythmia phenotype with dysregulated calcium transients, suggesting a novel micropeptide involved in regulation of the Sarcoplasmic-endoplasmic reticulum calcium (SERCA) pump. Strikingly, the micropeptides were found to be highly evolutionarily conserved throughout evolution, including in humans (Magny et al., 2013). In *Drosophila* development, the *mlpt/tal/pri* gene, discovered independently by several groups, contains four sORFs which appear to code for peptides (Zanet, Chanut-Delalande, Plaza, & Payre, 2016). Null mutants of this gene show dramatically dysregulated development, apparently due to disruption of a transcription factor (Zanet et al., 2015). In this case, the micropeptides appear in some fashion to regulate the ubiquitination and proteasomal degradation of the transcription factor. Finally, in the regulation of transcription, the micropeptide *pgc* was postulated to be a coding transcript by investigation of the Kozak sequence surrounding a translation start site (Hanyu-Nakamura et al., 2008). Synthesis and injection of the micropeptide into the embryo showed that it directly regulated phosphorylation of the CTD of Pol II, and immunoprecipitation showed that this was mediated by an interaction with P-TEFb. These three examples, unlike the above *Toddler* example above, show cases of

intracellular micropeptides regulating protein-protein interactions, in the case of *Sarcolamban* hydrophobic micropeptides regulating a membrane bound ion channel, and in the latter two cases soluble micropeptides regulating cytosolic interaction. Further, a recent genome-wide study by ribosome profiling has increased the number of candidate micropeptides in that genome to ~285, although most of these are of unknown function(Aspden et al., 2014; Zanet et al., 2016).

In mouse and human, finally, there has also been progress in identifying biologically relevant micropeptides, including the case of the *Toddler* peptide described above. Next, and also significantly, is the *Myoregulin* micropeptide, which followed on from the discovery of *Sarcolamban* in *Drosophila* already described(Anderson et al., 2015). Like *Sarcolamban*, the *Myoregulin* micropeptide regulates activity of the SERCA pump and thereby calcium transients, and similarly, it was found by bioinformatically screening newly discovered non-coding RNA transcripts for sORFs which could encode putative micropeptides. In this case, the screening was done by evolutionary conservation, and found a 46 amino acid peptide in a skeletal muscle-specific transcript. The peptide was found by labeling experiments to interact with the SERCA pump and have some homology to *Sarcolamban*, as well as to the human peptides *Phospholamban* and *Sarcolipin*(Anderson et al., 2015). Remarkably, the *Phospholamban* and *Sarcolipin* micropeptides have been known for some time as regulators of SERCA activity, but their tissue expression is limited to slow skeletal muscle and cardiac muscle, leaving a long-standing mystery as to how SERCA is regulated in other tissues; the *Myoregulin* peptide begins to solve this mystery. Further, extending work on the *Myoregulin* micropeptide, three more micropeptide members of the same family were found by screening the peptide binding motif of the family, discovering the micropeptides *Dwarf*(B. R. Nelson et al., 2016), *Endoregulin* and *Another-regulin*(Anderson et al., 2016). These peptides all regulate SERCA, and their

tissue distribution is substantially different, including tissues beyond muscle(Anderson et al., 2016), indicating that micropeptide-SERCA interactions are a widespread and perhaps fundamental system for regulating calcium transients in mouse and human.

Beyond bioinformatics screens of ORFs in ncRNAs, the human and mouse systems have also been substantially probed for micropeptides by ribosome profiling. A recent study in mouse embryonic stem cells found that many sORFs are indeed translated in these cells, and the majority of lincRNAs have translation levels comparable to annotated protein-coding genes, suggesting that many lincRNAs in fact encode micropeptides(Ingolia et al., 2011). The same study also observed widespread translation in upstream ORFs (uORFs) of known coding genes, which translation was downregulated during embryoid body formation. However, these latter observations cannot necessarily be taken to indicate functional micropeptides, since ribosome presence on a transcript means at most that a peptide is produced, but not that it is functional. For example, ribosome presence on upstream ORFs has canonically been interpreted as a regulatory process by which the ribosome's access to the main coding ORF is blocked, thus impeding translation of the main ORF(Hinnebusch, 2014). These uORF peptides, however, have been recently found to presented on MHC molecules, indicating at least a potential function in human immunity in some cases(Starck et al., 2016). Similarly, in human HEK293 cells, a recent ribosome profiling study found evidence of widespread translation in both uORFs and ncRNA-sORFs, and found evolutionary conservation of these translated ORFs(S. Lee et al., 2012). Once again, however, this cannot be taken to be definitive evidence of functional micropeptides.

In the human genome, annotation of micropeptides as to function has been somewhat limited, possibly by the complexity of the system; however, two functional micropeptides have been found, both in the human mitochondrial genome. The *Humanin* peptide, encoded by a short ORF from the mitochondrial DNA, was discovered some

years ago by a purely functional cDNA library screen for genes inhibiting apoptosis(Hashimoto et al., 2001). The cDNA was then confirmed to produce a peptide by discovery of its interaction with a cell-death regulator by a yeast 2-hybrid screen(Guo et al., 2003). More recently, the MOTS-c peptide, which regulates metabolism in some fashion, has been discovered in an sORF on the 12s rRNA gene in the mitochondrial genome by a bioinformatics screen of sORFs in mtDNA, showing a conserved 51 nt ORF with a strong Kozak context(C. Lee et al., 2015). Treatment of HEK293 cells with a synthetic peptide substantially regulated gene expression of enzymes involved in cellular metabolism, and treatment of mice fed a high fat diet prevented obesity, suggesting that the peptide is an extracellular signaling molecule.

Finally, substantial probing of viral genomes for micropeptides has also yielded some interesting results. Due to the small size of many their genomes, historically, viral genomes were not usually annotated with the explicit lower limits on the lengths of open reading frames, although the vaccinia virus, which has a large genome, had a lower limit of 65 codons for its original annotation(Goebel et al., 1990). Even without explicit minima during annotation, many viral micropeptides were simply overlooked because of systematic assumptions of how large genes should be, as genomes were annotated in an *ad hoc* fashion(Ratner et al., 1985). Micropeptides in viral genomes have been discovered in a similarly *ad hoc* manner, with several micropeptides found in influenza virus, human immunodeficiency virus, papillomavirus, poxviruses and paramyxoviruses(DiMaio, 2014). These micropeptides are often dominated by a single alpha-helical transmembrane domain, which allows them to be inserted into lipid bilayers, in which context they can interact with and regulate host cell proteins (i.e., HIV-1 Vpu), form ion-selective pores (i.e., influenza M2), allow binding and entry into host cells (i.e., poxvirus (O3L), or perform other functions crucial for the viral life cycle(DiMaio, 2014). These micropeptides are short genes which have been discovered

in genomes with many reading frames of such a size, and indeed, a recent genome-wide screen of human cytomegalovirus by ribosome profiling and mass spectrometry found ~484 novel ORFs shorter than 80 codons, including 245 shorter than 20 codons which were actively translated by the ribosome (Stern-Ginossar et al., 2012). These latter micropeptides must be validated by functional studies, but the high number identified here shows that there may be a substantial number of micropeptides produced by viruses.

It has been widely shown by a variety of methods, therefore, that despite underrepresentation in genome annotations, sORFs encode functional micropeptides in nearly all genomes studied, thus suggesting that there may be many micropeptides produced both from the human genome and from human pathogens that may be of relevance to human health. However, how many micropeptides there may be in genomes is still controversial. Many types of genome-wide approaches have given a wide range for how many coding micropeptides there are in the human genome, from tens of thousands to a few dozen (Andrews & Rothnagel, 2014). These problems reflect issues identifying sORFs which caused them to be overlooked in all genomes. In particular, it is difficult to detect evolutionary conservation of these ORFs, because their small size disrupts the statistical assumptions of homology detection algorithms such as BLAST or PhyloCSF (Couso, 2015). Thus, genome wide searches for conservation of sORFs incorrectly showed them to be unconserved. Secondly, very short peptides were thought to not have stable secondary structure, and thus, if biological function is assumed to be entirely dependent on the structure of the protein, short peptides could be assumed not to have a function (Ingolia et al., 2014; Wright & Dyson, 2015). This lack of secondary structure can also cause difficulties for genome-wide description of sORF-encoded micropeptides, for example by a biochemical method such as mass

spectrometry, since peptides without stable conformations may be rapidly degraded when cell are lysed for extraction(Hackett et al., 1986).

If these are reasons for micropeptide numbers to be underestimated historically, questions of artifact in newer methods may cause the number of functional micropeptides to be overestimated. In particular, each genome-wide method for micropeptide discovery can be prone to false positives for various reasons. Central methods which have been used to discover micropeptides genome-wide are ribosome profiling, mass spectrometry, RNA sequencing, and direct searches for conservation. In ribosome profiling, polysomes are extracted from cells, then treated with RNase to destroy RNA which is unprotected by ribosomes(Ingolia, Ghaemmaghami, Newman, & Weissman, 2009). The ribosome footprints are then sequenced, and these are used to map the positions of the ribosomes. These studies were some of the first to find translation of sORFs in the genome, and indeed found many ORFs translated from alternative start codons, which, if correct, would exponentially increase even the estimates of the number of potential sORFs in the genome(Ingolia et al., 2011). However, failure of RNase to digest a given section of the genome may be due factors besides ribosome content; in particular, RNA secondary structure may also block digestion, and RNA may also be underdigested due to sub-optimal reaction conditions. RNA-binding proteins may also block digestion. Furthermore, the mere presence of ribosomes in a given ORF does not necessarily demonstrate translation of that ORF. Certain features of ribosome profiling datasets, such as codon periodicity, can be used to determine 'genuine' translation, this continues to be controversial and as yet there is no definitive metric by which ORFs can be determined to be translated(Calviello et al., 2016; Guttman et al., 2013; Ingolia et al., 2014).

In RNA sequencing, the length of the transcript is sequenced, and the high sensitivity of this method has allowed many novel transcripts to be discovered. In

particular, RNA sequencing has recently discovered a large set of novel RNAs called long non-coding RNAs(Hart & Goff, 2016; Sun et al., 2013; Ulitsky & Bartel, 2013). These RNAs were originally believed to be non-coding because they contain no long ORF, but subsequent conservation analyses of short ORFs have revealed several of these lncRNAs to indeed be micropeptide-encoding(Anderson et al., 2015; Pauli et al., 2014). Thus, lncRNAs, which continue to be discovered by improved deep sequencing methods, may therefore be a large source of novel micropeptides. However, for the reasons mentioned above, most mainstream conservation analyses cannot be well applied to short ORFs, and thus, screening for conserved sORFs in lncRNAs to search for micropeptides likely underestimates the total number of sORFs, and indeed may account for why some lncRNAs were originally misclassified as non-coding. A recent attempt to address this problem, in which a novel conservation detection method was developed using an SVM classifier, some 2000 novel ORFs were found in the genome(Mackowiak et al., 2015). However, only a small percentage of these could be identified by mass spectrometry or ribosomal profiling data, raising the possibility that this paper overestimates the number of conserved sORFs. Thus, the number of micropeptides produced by newly discovered lncRNAs continues to be an open question. For these kinds of reasons, RNA sequencing experiments have not been able to provide a clear picture of how many micropeptides there may be in genomes.

Mass spectrometry for discovery of micropeptides also seems to run afoul of the underestimation problem. Firstly, as mentioned above, mass spectrometry attempts to directly detect micropeptides, and if it is correct that micropeptides are rapidly degraded by proteolytic enzymes after cell lysis, mass spectrometry thus may have problems with the speed of degradation of micropeptides after cell lysis. Secondly, lncRNAs are now known to be very low abundance in any given tissue(Cabili et al., 2015). Thus, detecting micropeptides translated from lncRNAs by mass spectrometry may have problems with

sufficient sensitivity. Indeed, across the literature one finds a mismatch between deep-sequencing based results and mass spectrometry, with deep-sequencing based results generally producing much higher numbers of micropeptides detected than mass spectrometry. There are two possible explanations for the latter phenomenon; first, mass spectrometry may underestimate, or deep sequencing may overestimate, the number of micropeptides in the genome, or both; second, ribosomes may bind to many ORFs promiscuously, but these peptides are either not translated or quickly degraded and non-functional. The former model implies that there are an undetermined number of micropeptides in the genome to discover, but the latter implies that there is no clear evidence that there is any substantial number of micropeptides in the genome.

Considering these issues, we propose that micropeptide discovery can be well-approached by the new technique of proteogenomics bioinformatics(Nesvizhskii, 2014), in which deep-sequencing data is used to generate candidate sequences to analyze mass spectrometry proteomics data. Mass spectrometry data must be searched against a database of candidate proteins in order to match experimental spectra to peptide sequences, and these databases have historically been lists of all annotated proteins from a genome(Eng, McCormack, & Yates, 1994); in proteogenomics, the database is produced by *in vitro* translation of a set of candidate sequences, from genomic or transcriptomic data. This allows mass spectrometry to orthogonally confirm ribosome profiling data indicating translation of micropeptides, and thus addresses the problem of the specific artifacts of each technical method to search for micropeptides genome-wide. Furthermore, we propose that since micropeptides are very low abundance, the sensitivity of mass spectrometry must be improved in order to discover them. We therefore here present a set of methods to discover micropeptides by mass spectrometry-based proteogenomics methods. In Chapter 2, we develop a novel method for online fractionation to improve sensitivity. This method can also be applied to

metabolomic profiling of cells and tissues, an application which we describe. In Chapter 3, these mass spectrometry methods are used to find micropeptides in HepG2 cells and HIV-1 purified virions, by combining mass spectrometry data with RNA sequencing data. Finally in Chapter 4, the proteogenomics approach is used to combine mass spectrometry and ribosome profiling data, to find a novel signaling micropeptide in the mouse CNS.

**Chapter 2: Integrated Microfluidic Chip and Online SCX Separation Allows
Untargeted Nanoscale Metabolomic and Peptidomic Profiling**

Abstract

In order to study micropeptides, mass spectrometry methods must be developed in order to capture them for analysis. We have here developed a two-dimensional LC-MS/MS system, which allows high-sensitivity detection of micropeptides in tissues. This was accomplished by liquid-liquid extraction of peptides and metabolites from tissue samples and online SCX separation to allow characterization of each population individually. The platform was validated both by a mixed set of purified standards for synthetic peptide sequences and by an analysis of splenic tissue from SIV-infected macaques, showing both good reproducibility in chromatography, with RSD of hold time less than 0.4%, and clear separation of charge states, with ~95% of molecular features in SCX separated runs at expected charge states. The system can indeed be used to detect micropeptides as short as a few amino acids. Secondly, we find that we can apply this system to perform metabolomics and micropeptidomics. These two molecular populations, metabolites and peptides, can be extracted from tissues in a similar fashion, and we therefore have here developed an integrated platform for their extraction and characterization. Finally, we used this platform to analyze the physiological response to infection in the spleen, showing that the spleen contains an abundance of hemoglobin-derived peptides, which do not appear to change in response to infection, and that there appears to be a large and variable metabolic response to infection. We therefore present a method for micropeptidomic and metabolomic profiling which is simple and robust.

Introduction

In recent years, the study of endogenous small molecule metabolites and endogenous peptides have both been greatly advanced by the application of high-throughput methods. These fields, now called “metabolomics” and “peptidomics” involve the study of a broad swath of the metabolite and peptide molecular content of cells or tissues.(Milne, Mathews, Myers, Ivanova, & Brown, 2013; Oliver, Winson, Kell, & Baganz, 1998; Patti, Yanes, & Siuzdak, 2012; Schulz-Knappe, Schrader, & Zucht, 2005; Tautenhahn et al., 2012) The results from these kinds of analyses can support “systems” analyses of cells or tissues under perturbed or pathological conditions, in which the integration of data on several molecular species allows a holistic picture of a biological response. Systems analyses therefore require methods by which several molecular species can be surveyed simultaneously. Furthermore, so-called micropeptides, which are produced by short open reading frames in genomes, can be discovered by mass spectrometry; however, since they are very low abundance, a high-sensitivity method for mass spectrometry must be used. Online fractionation can allow higher sensitivity for these low abundance analytes.

The metabolome consists of all small molecule intermediates of metabolism in a cell, and thus includes amino acids, nucleotides, fatty acids, lipids, and each of their various metabolites. It can thus be considered the molecular component of a cell which is not under the direct control of the genome.(Milne et al., 2013) The peptidome, similarly, is the complement of peptide species produced by a cell. Peptides and metabolites together perform significant biological functions, and thus their levels can be used for direct phenotyping of a biological system. For example, in the nervous system, peptides and small molecule metabolites of amino acids both function as neurotransmitters. Finally, study of the small molecule complement of tissues allows the

characterization of exogenous molecules, such as drugs and environmental exposures; the so-called “exposome.”(Wild, 2012) Therefore, since a profile of these species, micropeptides and metabolites, provides a useful molecular picture of a cell or tissue, we sought to develop a simple and robust means of simultaneously extracting and then analyzing them, by means of a single sample preparation and then an online LC-MS separation.

Here, we report the development of an HPLC-MS platform for simultaneous metabolomics and micropeptidomics. This was accomplished by integration of an online SCX separation into a nanoRPLC-MS/MS system. The platform was validated by a mixed set of small molecule and peptide standards, which showed separation into SCX fractions with good reproducibility. Applying our method to a tissue sample, we found that endogenous peptides seem to preferentially ionize in nanoESI, suppressing small molecule metabolite detection; these two molecular populations could be separated by our online SCX method, allowing both populations to be characterized. Finally, we used our platform to analyze the metabolome and peptidome of tissue samples in two biological conditions. Our platform thus provides an integrated workflow for fast and robust metabolite and peptide profiling in nanoLC systems already adapted for proteomics experiments, all in a combined MS analysis.

Methods

Reagents and Materials

Ascorbic acid, ammonium hydroxide, dithiothreitol, sodium chloride and HPLC-grade acetic acid, formic acid, methanol, and acetonitrile were acquired from Sigma-Aldrich (St. Louis, MO). Amicon 50,000 MWCO filters were obtained from Millipore (Bedford, MA). SDS sample buffer was obtained from Life Technologies (Carlsbad, California).

Atenolol, serotonin creatinine sulfate monohydrate, and 9-anthracene carboxylic acid were used at 100 μ M, 100 μ M, and 10 μ M, respectively, and were obtained from Sigma-Aldrich (St. Louis, MO). Peptide standards were used at 150 pM and obtained from Biognosys AG (Zurich, Switzerland).

Nanoflow HPLC-MS/MS System Profiling Method

For the online SCX method, we integrated one SCX column (150 μ m i.d. 2 cm length, Polysulfoethyl A, 5 μ m 300 Å, PolyLC) into the Agilent HPLC-MS system, which is comprised of a 1200 Infinity HPLC system coupled to an Agilent 6520 QTOF via an HPLC Chip Cube interface. The HPLC Chip contains an enrichment column to capture compounds and then a C18 analytical column, with rotor microvalve switching to bring the enrichment column in line with the analytical column for separation and injection.(Buckenmaier, Vollmer, Trojer, & Emotte, 2008) Thus, the whole sample metabolite extract was loaded onto the SCX column at 1.8 μ L/min and the flowthrough compounds captured by the enrichment column, prior to further separation by the C18 HPLC analytical column and MS detection. The SCX-captured compounds were eluted off the SCX column by injecting 6 μ L of 500 mM NaCl in 2% ACN/0.1% FA using the autosampler. The salt elution was captured by a C18 enrichment column integrated in the Agilent ultra-high capacity small molecule HPLC-Chip, (500 nL, 80 Å C18 trap with a 75 μ m i.d., 150 mm length, 80 Å C18 analytical column).

For both fraction injections (flowthrough and salt elution), desalting was done on the enrichment column in the HPLC Chip by washing with 6 μ L 3% ACN/0.1% FA. The rotor valve was then switched and HPLC gradient started at nanoflow, eluting the analyte from the enrichment column and separating it on the C18 analytical column. Elution of both fractions from the analytical column was performed using a gradient starting at 98% A, 2% B (A: 99.9% water, 0.1% FA; B: 89.9% ACN, 10% water and 0.1% FA) at 300

nL/min. The mobile phase gradient for both fractions was 2-98% B for 13 min, maintained at 98% B for 6 min, followed by re-equilibration of column with 2% B for 5 min.

Nanoflow HPLC-MS/MS System Shotgun Method

An online SCX column fractionation method was used as described for the profiling method. Data dependent acquisition mode was used for MS acquisition by an Agilent 6520 QTOF. Precursor MS spectra were acquired within the m/z range 315 to 1700 and the top 4 peaks were selected for MS/MS analysis. Product scans were acquired within the m/z range 50 to 1700 at a scan rate of 1.5/second. A medium isolation width (~ 4 amu) was used, and a collision energy of slope 3.9 V/100 Da with a 2.9 V offset was applied for fragmentation for peptide acquisition, while a fixed collision energy of 10 and 20 V was applied for metabolite acquisition. A dynamic exclusion list was applied, with precursor exclusion of 0.50 min after two MS/MS spectrum was acquired.

Bioinformatics Analysis

Molecular Feature Extraction was performed using the Agilent MassHunter Qualitative Analysis program, version B.04.00. Centroided peaks were filtered at 5,000 counts and the chromatographic small molecules extraction algorithm was used. Allowed adducts were H^+ and Na^+ . Charge state determination was unrestricted to avoid improper charge state assignment. For isotope grouping, peak spacing tolerance was 0.0025 m/z plus 7 ppm, and an isotope model of common organic molecules was used. For peptide identifications, Mascot (version 2.2) was used with variable modifications of oxidation of methionine and carbamylation of cysteine. Database was constructed in-house with sequences from SwissProt with a Mammals taxonomy limitation and HIV and SIV sequences (66,813 sequences). The search results were filtered and annotated in

MASPECTRAS 2.0;(Ubaida Mohien et al., 2010) filtering was done with a minimum of two peptides per protein. For metabolite identifications, the METLIN database was searched using the MassHunter Qualitative Analysis program (Agilent Technologies, version B.04.00) with precursor and product m/z expansion of $10 \text{ ppm} \pm 2 \text{ mDa}$ and $20 \text{ ppm} \pm 2 \text{ mDa}$, respectively, relative height of 0.5%, no collision energy limitation, and minimum reverse score of 80. For quantitative profiling, Mass Profiler (Agilent Technologies, version B.03.00) with default settings of minimum relative frequency of 70% in at least one group and minimum differential score of 85% was then used to align runs, and all features, along with annotations for number of runs aligned, were exported to spreadsheets for further analysis.

Results and Discussion

We sought to develop a method for profiling both metabolite and micropeptide species simultaneously. We noted, firstly, that peptide species and small molecules can be made to co-partition in a Bligh-Dyer extraction.(Sana & Fischer, 2007) Secondly, peptide species become more highly charged in acidic conditions (i.e., $\text{pH} < 3$) than smaller metabolites. We hypothesized, therefore, that peptides and metabolites could be extracted together in a modified Bligh-Dyer reaction and then separated by an online SCX column. Therefore, we integrated a short SCX column into the HPLC Chip Cube system, in line with the autosampler. In this platform, the biosample extract can be injected and loaded onto the SCX column, while the SCX flowthrough is captured by the enrichment column on the HPLC Chip. We have developed a similar method for online multidimensional proteomics.(Tao et al., 2014) The captured flowthrough is then eluted from the enrichment column to the analytical column and analyzed by MS. As the loading buffer is acidic, the SCX flowthrough should contain small molecule metabolites, as these collect less charge in acidic conditions. The captured peptides are then eluted

by an injection of high salt buffer and loaded onto the enrichment column for desalting, then in turn eluted and analyzed by MS and MS/MS (Figure 1).

We first tested our platform for separation and reproducibility with a mix of purified standards. In order to apply the platform to a range of possible analytes, we used one bioactive endogenous small molecule, serotonin, one exogenous pharmacological compound, atenolol, and one polycyclic aromatic hydrocarbon, anthracene carboxylic acid, as an environmental compound. These were combined with three synthetic peptides (Table 1). The small molecule and peptide species were well separated by the SCX column, and chromatography was highly reproducible, with RSD of reproducibility at hold time of no greater than 0.4% (Figure 1, Table 1).

We next applied our LC-MS platform to the analysis of tissue sample extracts containing both peptides and metabolites. Mammalian spleen tissue is a mix of both liquid and solid biological matrix, since the spleen contains an open blood circulation which is filtered through sinusoids composed of structural and immune cells. (Mebius & Kraal, 2005) As such it provides a useful test sample for a profiling method such as ours. Four spleen homogenates from rhesus macaques were suspended in methanol and chloroform to precipitate proteins, and the aqueous (upper) phase collected to remove lipids. The resulting peptide and metabolite extracts MS runs were run in triplicate. The MS results show a significant change in the charge state distribution of the SCX flowthrough fractions vs. the high salt elution, with the vast majority (~95%) of molecular features in the flowthrough at +1 or +2, while the high salt elution produced a large range of charge states in a distribution centered around +4, with ~76% at charge states >2 (Figure 2b). By contrast, when the same samples were run without SCX fractionation, we observed only the broad charge state distribution (Figure 2a). We thus show that the SCX system reproducibly separates analytes by charge state.

The charge state distributions thus suggested that, when samples were run without SCX separation, peptide species preferentially ionized and suppressed detection of small molecule metabolites. Indeed, when MS/MS was performed on both peptides and metabolites in a “shotgun proteomics-like” manner, in which masses were acquired and fragmented with a rolling exclusion window, peptide suppression was reflected in a high percentage of features identified as peptides by a Mascot search, with a correspondingly low level of identifications of metabolites by a METLIN search (Figure 2c). In this experiment our SCX platform produced an improvement of 2- to 5-fold in metabolite identification (Figure 2d). We also found that the peptide population was shifted into the high-salt elution fractions (Figure 2e), showing that the high charge state features were accounted for by peptide. Peptide identifications were derived from degradation products of hemoglobin (Table S1), which was not unexpected from aqueous phase extractions from spleen, in which red blood cells are reprocessed and hemoglobin catabolized.

The overall metabolite identification results from the HPLC-MS metabolomics and HPLC-MS/MS “shotgun” metabolomics experiments are shown in Table S2 (identified by both accurate mass and MS/MS spectra), Table S3 (identified by MS/MS spectra), and Table S4 (identified by accurate mass alone). Metabolites identified by both MS and MS/MS spectra were primarily single amino acids, and identifications only by MS/MS spectra also contain many single amino acids. Finally, by accurate mass (AM) alone we find a large number of candidate small molecules. As these identifications are only by AM, they should not be considered absolute identifications, and it would be necessary to confirm by running purified standards. Nevertheless, we show here that we can profile small molecules and peptides by our nanoflow-SCX system, especially, in this case, bioactive amino acids. Our SCX-nanoRPLC-MS system, therefore, allows

metabolomics and peptidomics profiling experiments for qualitative metabolite identification.

Finally, in order to test whether our system could be used to discover pathological differences in the metabolome and peptidome in tissues in a disease state, we applied the system to find metabolomic and peptidomic changes in SIV-infected spleen tissues compared with healthy controls. This macaque model of SIV is well characterized and contains clear peripheral inflammation during the acute phase of infection.(Clements, Mankowski, Gama, & Zink, 2008; Dinoso et al., 2009; Mankowski, Clements, & Zink, 2002) Here, metabolites and peptides were extracted as above, with 6 spleens derived from SIV-infected macaques and 6 derived from uninfected control macaques. In order to maximize metabolite yield, extractions were performed at three different pH levels and the extracts combined. Metabolite and peptide species were analyzed by the platform as described above. LC-MS runs were aligned and features that aligned in greater than 80% percent of runs were quantified. Although we find no significant differences in particular metabolite features, possibly reflecting a large variability in the response to infection in particular biochemical pathways, we find differences in clustering by PCA in features derived from the SCX flowthrough fractions (Figure 3). In particular, while control uninfected animal tissues clustered closely together, the metabolomes of the infected tissue were spread widely, suggesting a response to infection which was variable at the level of particular metabolites. No significant differences were observed in peptide levels (Table S5). We speculate that while there may be no changes in the hemoglobin content of the spleen during acute infection, the infected spleens are undergoing tissue-level and cellular population changes which cause these metabolomic differences. However, we cannot rule out that there may be significant changes in particular metabolites or peptides which are not

being detected by our platform, and it is possible more sensitive metabolomic methods may detect differences in particular metabolites. Finally, we must note that biopsies were taken without any knowledge of the local anatomy of the frozen spleen tissue, which may mean that some biopsies from infected samples may have included splenic zones such as germinal centers, while some did not, and this may account for some of the variability we see in the metabolic response. Nevertheless, the data shows that the SCX-nanoRPLC-MS method can provide reproducible chromatography and allows metabolomic and peptidomic profiling which detects biological differences across treatment conditions.

Conclusion

In this work, we present a method for profiling of metabolite and peptide extracts from whole tissue samples. We find that nanoflow metabolomic profiling of tissue may be substantially suppressed by peptide ionization and this suppression may be avoided by a simple and robust system whereby peptides and metabolites are separated by online SCX fractionation. Thus, our system allows extraction of a large range of metabolites and peptides from tissue samples and their simultaneous characterization in a single sample injection. While offline SCX separation has previously been used to purify metabolites before analysis, we know of no other integrated online separation system such as ours, which allows immediate analysis of both species. Furthermore, we show that the SCX-nanoRPLC-MS method produces chromatography which is sufficiently reproducible for quantitative profiling. Most importantly, this method is easy to implement, as it requires only the addition of an SCX column, and it utilizes the same chromatography buffers as most proteomics experiments. We believe this will make metabolomics more accessible to labs already using nanoHPLC for protein identification. Finally, although we have not attempted this here, we speculate that if protein samples

were to be digested and then precipitated in our modified Bligh-Dyer, this method could be used for simultaneous metabolomics and proteomics in the same analysis run. We therefore believe that this method may be useful for the development of integrated systems biology approaches combining metabolomics and peptidomics.

Figure 1. Schema and EIC of online SCX separated metabolite and peptide

standard mixtures. Three metabolite standards, Atenolol (100 μ M), Serotonin (100 μ M)

and 9-anthracenecarboxylic acid (10 μ M), and purified peptides TPVISGGPYER, GDLDAAASYAPVR and DAVTPADFSEWSK (150 pM). Mix of three small molecule standards and three peptide standards were run in replicate injections, with HPLC separation only and with SCX separation online with HPLC separation. *A*, small molecule (top) and peptide (bottom) signals for replicate runs separated by HPLC alone. Metabolite and peptide mix is first desalted on an enrichment column and then eluted by an acetonitrile gradient into the MS. *B*, small molecule (top) and peptide (bottom) signal for SCX flowthrough of replicate runs separated online by both SCX and HPLC. Peptides are captured on an SCX column, and the metabolites are desalted on an enrichment column, then eluted and analyzed by MS. The peptides are then eluted from the SCX column by a 500 mM NaCl injection, then desalted on the enrichment column, and then eluted and analyzed by MS. Each replicate sample run is coded by color, y-axes are ion counts and x-axes are retention times in minutes. See text for chromatographic workflow.

Figure 2. SCX separation alleviates peptide contamination of nanoflow metabolomic profiling experiments and allows characterization of both species.

(A) Charge state distribution as a percentage of total features for an unseparated sample. 4 spleen homogenates were analyzed in triplicate by MS and molecular features extracted, percentages were averaged over all 12 runs. Charge states greater than +1 suggest peptide species. **(B)** Charge state distribution as a percentage of total features for SCX separated sample. 12 spleen homogenates were analyzed by MS with an SCX column placed inline with the autosampler, and high salt washes run after each sample run. Molecular features were extracted and percentages were averaged over all 12 runs. **(C-E)** Number of peptides identified by Mascot and number of metabolites identified by METLIN search, as percentage of total features extracted, from **(C)** unseparated sample, **(D)** SCX flowthrough runs, and **(E)** high salt elutions. Error bars are 95% CI, p-values are by two-tailed Mann-Whitney U Test.

Figure 3. Principal Components Analysis for control and infected metabolite samples analyzed by online SCX system. PCA shows differences between control and infected samples. Control animals are clustered together (Red, n=6) and show a clear separation from infected (Blue, n=6), which are widely spread, showing strong but variable response to infection. The PCA components are represented as X, Y and Z, where X axis is PCA component 1 (accounts for 48.73%), Y axis PCA component 2 (24.86%) and Z axis PCA component 3 (10.99%) according to their decreasing significance.

Table S5d. Quantitation by features in peptide detection SCX runs. Control vs infected comparison.

Table S5. Peptide features extracted for high salt runs. Nanoflow-SCX high salt elution runs were profiled for endogenous peptide features, and retention time and peak areas were quantified by MassHunter.

Supplemental Methods.

Animal Infection Protocol

Six juvenile pigtailed macaques (*Macaca nemestrina*) were infected with SIV by intravenous inoculation with both an immunosuppressive swarm (SIV/DeltaB670) at a dose of 10,000 times 50% animal infectious dose and a neurovirulent clone (SIV/17E-Fr) at a dose of 50 times 50% animal infectious dose, as described previously. (Clements et al., 2008) Sacrifice and necropsy were at 7 days post-infection. Negative controls were six juvenile pigtailed macaques, mock inoculated with PBS and then sacrificed. Spleen tissue samples were collected from all 12 macaques and fresh frozen. Animal protocols were approved by the Johns Hopkins University Institutional Animal Care and Use

Committee in accordance with Animal Welfare Act regulations and the USPHS Policy on Humane Care and Use of Laboratory Animals.

Animal Studies Ethics Statement

“Animal studies were approved by the Johns Hopkins Animal Care and Use Committee (IACUC protocol #PR12M310); animals were humanely treated in accordance with federal guidelines and institutional policies. Pigtailed macaques (*Macaca nemestrina*) used in this study were obtained from nonhuman primate breeding facilities within the United States, and were housed in Johns Hopkins University facilities that are fully accredited by the association for the Assessment and Accreditation of Laboratory Animal Care, International (AALAC). All housing met or exceeded guidelines of the National Institutes of Health “Guide for the Care and Use of Laboratory Animals” and the United States Department of Agriculture Animal Welfare Act. Macaques were fed a balanced, commercial macaque chow (Purina Mills, Gray Summit, MO, USA) once a day supplemented with a variety of food enrichment.”

Tissue Sample Collection and Preparation

Miltex 3 mm biopsy punches of fresh-frozen spleens were resuspended in 500 μ L 0.1% ascorbic acid in a 1 mL Kontes Duall Tissue Grinder, and homogenized by hand for 10 minutes. Metabolites were extracted by a modified(Sana & Fischer, 2007) Bligh-Dyer protocol: 150 μ L homogenate was added to 600 μ L methanol at -20°C. 450 μ L room-temperature chloroform was then added, and the solution vortexed and returned to an ice bath. The solution was then vortexed every 5 minutes for 30 minutes, returning to the ice bath each time. At the penultimate step, 150 μ L ice cold MilliQ water was added, and samples were maintained at -20°C for 2 hours to create phase separation. The upper (aqueous) phase was then collected.

Next, in order to maximize metabolite yield, the above extraction procedure was repeated with 2% ammonium hydroxide at pH 9, and with 1% formic acid at pH 2. Specifically, the organic phase from the first extraction was dried and then resuspended in water. The methanol and chloroform steps were repeated as above, and then the pH 9 buffer was added to create the phase. The aqueous phase following this step was collected, and the procedure was repeated with a buffer at pH 2. All three extractions were filtered with a 50,000 MWCO to remove large particulates, and flowthroughs were combined, dried, and resuspended in 2% ACN/0.1% FA for HPLC-MS analysis.

Protein Normalization for Quantitative Profiling

For quantitative metabolite profiling, protein amounts in each homogenate were estimated by a modified Lowry method after a deoxycholate precipitation (2D Quant Kit, GE Healthcare). Protein estimations were confirmed by 1D gel electrophoresis and SYPRO Ruby (Life Technologies) staining. For gels, 2 µg sample was combined with 2.5 µL SDS sample buffer, and 1 µL 100mM DTT, and the final solution diluted up to 10 µL with MilliQ water. Running buffer was prepared by diluting MES SDS running buffer (Life Technologies) 1:20 in MilliQ water with 20% methanol. Samples were denatured for 10 minutes at 70°C, and run for ~40 minutes at 200 V constant voltage.

Chapter 3. Micropeptidomics by RNAseq and proteomics.

Introduction

In the previous chapter, we have developed a high-sensitivity peptidomics method to detect low-abundance novel micropeptides in various genomes. We now apply this method to biological samples in order to discover micropeptides being translated. First, in this chapter, we apply the method to the HepG2 cell line, which is a widely used line (Mersch-Sundermann, Knasmüller, Wu, Darroudi, & Kassie, 2004). Such studies will inform both cases in which this cell line is used as a model for hepatocellular carcinoma (Samarakoon, Thabrew, Galhena, & Tennekoon, 2012) as well as cases in which HepG2 is used in other model systems, such as in malaria infection (Chattopadhyay et al., 2011). In order to discover novel genes by proteomics, it is necessary to include candidates of novel genes in the database used to search the mass spectrometry data. In this study, we have developed a strategy for generation of databases which include both known genes and novel micropeptides, in order to facilitate novel micropeptide discovery by RNA sequencing by searching an *in silico* translation of the transcriptome. Thus, the combination of our novel LC-MS/MS method and the novel bioinformatics method developed here allows the discovery of micropeptides encoded by the human genome. In a second experiment, we searched in a human pathogen genome, the HIV-1 genome, for novel micropeptides, using a similar strategy of high-sensitivity mass spectrometry for acquisition of spectra from micropeptides and then our bioinformatics technique to detect translation of novel micropeptides.

Methods

HepG2 experiment.

HepG2 dataset. The HepG2 cell line proteomics dataset was downloaded from the ProteomeXchange Consortium(Deutsch et al., 2017) by the dataset identifier PXD000682. In that study(Deutsch et al., 2017), HepG2 cells were treated or untreated with HGF (50 ng/ml, for 24 hours), then subcellular enrichment was performed upon cellular lysis to enrich for membrane or cytosolic proteins. Soluble proteins were extracted by 4 cycle freeze thaw in the presence of protease inhibitors. The cell remainder was pelleted, and membrane proteins were extracted by lysis in SDST buffer. Finally, both sets of lysates were fractionated by the 2D strong cation exchange system described in Chapter 2 of this thesis, fractionating each sample run into 0, 15, 30, 45, 60, 120, 160, and 300 mM NaCl fractions which were analyzed online. All fractions were re-combined for peak-picking to produce a single Mascot Generic Format (MGF) file, in a Multidimensional Protein Identification Technology (MuDPIT) strategy(Kislinger, Gramolini, MacLennan, & Emili, 2005). The datasets from that publication which were re-analyzed for this publication are detailed in Table 1. Briefly, datasets from three biological replicates of the HGF experiment were re-analyzed. For the first replicate, 2 replicate injections of the membrane extraction and 3 replicate injections of the cytosolic extraction for the HGF treated cells were used, and 2 replicate injections of the membrane extraction and 4 replicate injections of the cytosolic extraction of the HGF-untreated cells were used. For the second replicate, 2 replicate injections of the membrane extraction and 4 replicate injections of the cytosolic extraction of the HGF treated cells were used, and 2 replicate injections of the membrane extraction and 4 replicate injections of the cytosolic extraction of the untreated cells were used. For the third replicate, 1 injection of the membrane fraction, and 2 replicate injections of the cytosolic extractions of the HGF-treated cells were used, and 1 replicate injection of the membrane extraction and 2 replicate injections of the cytosolic extraction of the

untreated cells were used. Not all replicate datasets of the original publication were used, in order to minimize the computational resources necessary.

HepG2 Analysis transcriptome assembly and database generation. Assembled transcriptome for HepG2 cells was obtained from the ENCODE project data(Djebali et al., 2012). A database of all possible transcribed open reading frames was generated using the EMBOSS tools through Galaxy version 5.0.0: the getorf(Blankenberg et al., 2007; Rice, Longden, & Bleasby, 2000) tool was used with standard codon table with alternative start codons (NUG) recoding Met for alternative start, a minimum open reading frame size of 15 nucleotides, corresponding to 5 amino acids(Koskinen, Emery, Creasy, & Cottrell, 2011), and a max of 300 nucleotides, corresponding to 100 amino acids, encompassing the ORF size range from 5-100 codons. Open reading frames were considered as translated regions from start to stop codons, rather than from stop to stop codons, and the translated sequences were output rather than the nucleic acids. All start codons were forced to code for methionine including alternative start codons(Peabody, 1989). Circular sequences were not allowed, ORFs were not searched in the reverse complement sequences (as this is transcript, not genomic, data), no flanking nucleotides were output, and output format was NCBI FASTA. The database thus generated was concatenated with Swissprot(The UniProt, 2017) delimited for taxonomy to human, and the final database contains 1,313,498 protein sequences.

HIV-1 experiment.

HIV-1 isolation and purification. Three lab isolates of HIV-1 were used for this study: first, virus produced from the NCI's HIV-1(MN)/H9 CL.4 cell line, which is a cell line containing a single active provirus cloned by limiting dilution(Ott, Nigida, Henderson, & Arthur, 1995); second, virus produced from the NCI's HIV-1(MN)CL.4/CEMx174(T1) cell line(Salter, Howell, & Cresswell, 1985), which is a B cell/T cell hybridoma cell line,

infected with the cloned virus above; third, virus produced from the NCI's HIV-1 ADA/SUPT1-CCR5 CL.30 cell line(Del Prete et al., 2009), which is infected by a swarm of viruses produced by infecting human primary peripheral blood mononuclear cells with the HIV-1 ADA strain. These three viruses were used as three biological replicates in which to search for novel virus-encoded micropeptides. Viral purification was done by continuous flow ultracentrifugation in a sucrose density gradient, followed by direct pelleting to remove sucrose. All preparations were then treated with aldrithiol-2 to render virions intact but uninfecious(Rossio et al., 1998) before further biochemical processing.

Deep sequencing of HIV-1 genomes. Random hexamers were used to prime first-strand cDNA synthesis of viral RNA in a genome-wide, unbiased fashion(Hughes et al., 2012). Libraries were then prepared from vRNA by a Nextera tagmentation kit and sequenced by MiSeq by standard protocols.

Protein extraction from purified HIV-1 virions. Virions were secondarily destroyed and inactivated by the addition of 3 volumes of methanol, and the protein allowed to precipitate and pelleted. The pellet was dried and lysed in a standard Urea-based proteomics lysis buffer (8M Urea, 2M Thiourea, 2% CHAPS, 2% ASB-14, 1% Triton X-100, 1% Triton X-114, 10 mM DTT, 150 mM NaCl, 50 mM Tris) for an approximate concentration of 1 mg/ml. Reduction and alkylation was performed, then all detergents were removed by methanol/chloroform precipitation. The remaining pellet was then resuspended in a standard Urea-based proteomics buffer without detergent (8M Urea, 2M Thiourea, 25 mM DTT, 100 mM NaCl). Trypsin digestion was then performed by diluting protein solution to 2M by addition of ammonium bicarbonate to a final concentration of 50 mM, and trypsin was then added at 1:80 trypsin:protein ratio. Digestion was performed at 37°C for 24 hours with agitation. Samples were resuspended in 3% buffer B for HPLC desalting (90% acetonitrile, 9.9% water, 0.1%

formic acid), and desalted using a C18 column on an Agilent 1200 HPLC system with an 11 minute HPLC protocol: 4 min, 3% B, 4 min 99% B, 3 min 3% B with a flow rate of 500 uL/minute, with UV detection at 214nm for peak collection. Sample was collected and desalted twice.

Mass spectrometry proteomics analysis. Mass spectrometry of HIV-1 derived purified tryptic peptides was performed by an ABSciex 5600 TripleTOF mass spectrometer running in data-dependent acquisition (DDA) mode using an online Eksigent NanoLC 400 HPLC system. Peptides were resuspended in buffer B (0.1% (v/v) formic acid, 90% (v/v) acetonitrile) and run on a 105 minute HPLC gradient of 10-98% buffer A (0.1% (v/v) formic acid, 2% (v/v) acetonitrile) at a flow rate of 750nL/min. MS/MS spectra were collected in the range of 100-1500m/z. All three samples were run in triplicate, and replicates were analyzed together.

HIV-1 genome assembly and database generation. Assembly of genomes was performed with Trinity de novo assembler(Grabherr et al., 2011) (Trinity Galaxy version 0.0.1). The group pairs distance was set for 500 nucleotides, the path reinforcement distance was set at 75 nucleotides, the minimum kmer coverage for contig construction was set to 1, the max transcript reads per graph was set to 2,000,000, and the minimum contig length was set to 200 nucleotides. Since the transcripts (RNA genomes) thus assembled were only considered to produce candidates for the proteomics search, the assembler settings were not optimized. Databases were produced from all three HIV-1 strains described above, in a manner identical to that for the HepG2 study, and as above, each database was concatenated to the human Swissprot database, since HIV virions are well known to contain human host proteins, and viral purifications can also contain host cell exosomes of the same density as virions, which may also contain both human and viral proteins. For the HIV-1(MN)/H9 CL.4 virus, this analysis produced

34,834 candidate novel protein sequences, which after concatenation expanded to 55,485 sequences. For the HIV-1(MN)CL.4/CEMx174(T1) virus, this analysis produced 41,366 candidate novel protein sequences, which after concatenation expanded to 62,017 sequences. For the HIV-1 ADA/SUPT1-CCR5 CL.30 virus, this analysis produced 48,641 candidate novel protein sequences, which after concatenation expanded to 69,292 sequences.

Bioinformatics analysis for both experiments.

The datasets detailed above were searched with Mascot version 2.5.1.2 (Matrix Science, London, UK)(Perkins, Pappin, Creasy, & Cottrell, 1999), and the protein identification results from these Mascot searches were further analyzed in Scaffold 4.4.5(Proteome Software, Portland, OR, USA) in a subset database search approach(Tharakan, Edwards, & Graham, 2010) with X!Tandem CYCLONE(Fenyo & Beavis, 2003), version 2010.12.01.1. Both Mascot and X!Tandem searches were run with a parent ion mass tolerance and fragment ion mass tolerance of 50 ppm and 0.60 Da, respectively. Two missed cleavages were allowed. Variable modifications were set in Mascot as deamidation of asparagine and glutamine, oxidation of methionine, carbamylation of lysine and carbamidomethylation of cysteine. In the X!Tandem subset database search, the variable modifications list was allowed to expand to take advantage of the smaller search space (cite), allowing conversion of glutamate or glutamine to pyroglutamate at the N-terminus, ammonia-loss of the N-terminus, deamidation of asparagine and glutamine, oxidation of methionine, carbamylation of lysine and carbamidomethylation of cysteine. Both peptide and protein identifications were accepted if they could be established at greater than 95% probability by the PeptideProphet algorithm(Keller, Nesvizhskii, Kolker, & Aebersold, 2002) with Scaffold delta-mass correction and by the ProteinProphet algorithm(Nesvizhskii, Keller, Kolker, & Aebersold, 2003), respectively.

Results and Discussion

In order to discover novel micropeptides in the human genome, we took a proteogenomics approach to the HepG2 cell line. We used RNA sequencing data from the ENCODE project to assemble a database of all possible short open reading frames which are transcribed in that cell line. This database was then concatenated with a database of known, well-annotated human proteins, Swissprot. This large database thus contains known human proteins as well as potential proteins which could be transcribed from short open reading frames. Concatenation is necessary in order to prevent many spurious proteomic matches by known human proteins to the short open reading frame (sORF) database, which, since they will overlap with many sORFs in the transcriptome, such as alternate start site sORFs, are not unambiguously identified from proteomics data(Vanderperre et al., 2013). For this reason, the database is first concatenated with a generic known protein database, and so any alternate frame sORF will be mapped twice, both to the sORF database entry and to the known protein database entry. For these hits, we consider them not to be unambiguously identified as micropeptides, since any alternate start internal sORF will be matched if its corresponding canonical protein is matched. Furthermore, since the SwissProt database is well-annotated, but does not contain all known human proteins, we cannot assume that all possible ambiguous coding frames mapping to a known human gene can be eliminated by this process(The UniProt, 2017). Therefore, we use a second step of filtering to eliminate alternate coding open reading frames which are not represented in the SwissProt database, by using BLAST searches(Altschul, Gish, Miller, Myers, & Lipman, 1990) against all protein sequences represented in NCBI nr, which is a comprehensive and highly redundant

protein database. The protein BLAST matches were then evaluated for whether the transcripts they mapped to could be considered to be novel or not.

The complete list of proteins identified in the HepG2 proteomics analysis is shown in Table 2. Allowing a threshold of 95% confidence (see Methods), produces a dataset of 2864 proteins, with .3% peptide FDR and 1% protein FDR. These proteins can be clustered by shared peptides, assuming that proteins that share peptides cannot be unambiguously identified, and that proteins that share peptides are similar enough in sequence to be similar in function or isoforms of each other (Ubaida Mohien et al., 2010). Clustering the proteins in this manner reduces the protein list to 2629 clusters of similar, undifferentiable proteins. Thus, the analysis identifies a large component of the proteome successfully, a proof of principle that the analysis can be used to discover novel peptides as well. A second validation is that proteins which would be expected to be enriched in their respective fractions are indeed enriched. Table 3 shows proteomic identifications separated into HepG2 HGF treated and untreated, and into membrane and cytosolic fractions. Estimates can be derived in a general manner by spectral counts (Choi, Fermin, & Nesvizhskii, 2008). The table shows that several proteins which are expected to be enriched in cytosolic fractions were indeed enriched. For example, the chaperone proteins heat shock protein 90a and 90b are both enriched in the soluble fraction, which is to be expected since they are primarily cytosolic (Wandinger, Richter, & Buchner, 2008). Similarly, UQCRC2 (Hosokawa, Suzuki, Toda, Nishikimi, & Ozawa, 1989), which is a component of Complex III of the respiratory chain, is found only in fractions processed for membrane enrichment, as is ATP Synthase 5B (Neckelmann et al., 1989). However, many of the membrane-enriched proteins are soluble proteins found in membrane-enclosed fractions, such as lamins (Gruenbaum, Wilson, Harel, Goldberg, & Cohen, 2000) and histones (Marino-Ramirez, Kann, Shoemaker, &

Landsman, 2005) in the nucleus, suggesting that the membrane fraction may better be considered a non-cytosolic fraction. Finally, the analysis is also validated by the probability distributions generated by the PeptideProphet (Ma, Vitek, & Nesvizhskii, 2012) algorithm. As the algorithm is described, two distributions are generated from the protein scores of all proteins, both of which follow a Gaussian distribution. If the Gaussian model fits well to the distributions of scores, the lower distribution can be considered a distribution of 'incorrect' matches, while the higher distribution can be considered correct matches. If the dataset is too sparse, the distributions cannot be modeled and the probabilities are not accurate. Figure 1 shows the distributions modeled by the PeptideProphet algorithm for this analysis, for charge state +2, showing that the probabilities thus calculated can be considered accurate.

After filtering by probability as described, the list of 2629 clustered proteins contains 27 proteins which map to sORFs from the HepG2 ENCODE transcriptome without any shared peptides with known proteins. Of these, only 2 survived the BLAST homology filtering step described above, with the remainder found to be homologous with known proteins. These latter two can be considered to be novel micropeptides discovered by our proteogenomics approach. The first peptide, shown in Figure 2, is represented by a single spectrum, which has fairly good coverage but several unidentified peaks. The peptide is produced from the gene SLC35A3 (Ishida, Yoshioka, Chiba, Takeuchi, & Kawakita, 1999), which is a UDP-GlcNAc transporter in the Golgi apparatus. The transcript is 5708 nt long, with a ~1100 nucleotide CDS and a long (~4500 nucleotide) 3'UTR. The 12-codon ORF is in the 3'UTR of the transcript at positions 5410-5448, and has an alternative start leucine codon which is recoded as NUG to Methionine, for a final translation of MSVCCFICNYKII. The peptide is detected only in the membrane fractions. The second peptide, shown in Figure 3, is represented

by 4 spectra, which are shown in 4b. The spectra appear to have a clear B and Y series, but do also contain prominent unidentified peaks. The peptide hit is contained in gene WASHC4(Ropers et al., 2011), which has a transcript 5812 nucleotides long, with a ~3500 nucleotide CDS and a long (~2300 nucleotide) 3'UTR. The 3'UTR contains a 34-codon ORF at positions 4154-4255 with an in-frame stop. The translation initiation site is a leucine codon recoded to methionine, in a second case of alternative initiation. The peptide, like WASHC4 itself, is detected only in soluble proteome fractions. The translation product sequence is MMILLSLLISCDSQELLMSLMRHFITSLHCFENI, of which a tryptic portion is detected, ILLSLLISCDSQELLMSLMR. In both these cases, long 3'UTRs produce cryptic micropeptides in transcripts which have that structure. This is similar to a case described in another SLC transporter-class protein, in which SLC35A4 was found to produce a cryptic micropeptide from a long 5'UTR(Andreev et al., 2015). Thus, this proteogenomics analysis can be shown to be robust for describing the proteome in a normal fashion, and also finds translation of at least one (from the WASHC4 transcript) and possibly two novel micropeptide genes.

In a second approach to discovering novel micropeptides in genome, we targeted an important human pathogen, HIV-1. We produced proteomic and genomic data from three HIV-1 lab isolates: first, a virus grown from HIV-1(MN)/H9 CL.4, a cloned cell line infected with a single HIV-1 clone; second, a virus grown from HIV-1(MN)CL.4/CEMx174(T1), an uncloned cell line infected with many different HIV-1 clone, and producing them all; and third, HIV-1 ADA/SUPT1-CCR5 CL.30, which is an uncloned cell line infected by a swarm of HIV-1 viruses produced from human primary PBMC (J. Bess, Personal Communication, and see Methods). The viral isolates could thus be considered to have increasing levels of genomic heterogeneity. The three viral isolates were analyzed by proteomics; in this case, a higher-sensitivity mass

spectrometer was used (see Methods) obviating the need to use 2D fractionation for high sensitivity. In parallel, viral RNA was extracted from each isolate and their genomes sequenced. These sequences were assembled *de novo* into sets of putative HIV-1 genome sequences, and a database was generated from them using methods similar to that used for the HepG2 experiment above. Finally, these proteomics datasets was searched against the databases thus generated in a proteogenomics approach to novel micropeptide discovery.

De novo assembly generated several thousand genomic sequences for each isolate (see Methods). We emphasize that these sequences should not be taken to demonstrate that each viral isolate has many thousands of completely divergent genomic sequences. Indeed, *de novo* assembly is difficult and all known *de novo* assemblers are adapted for cellular transcriptomes, rather than the viral ssRNA genomes. However, we nevertheless argue that we can use the genomic sequences thus assembled as candidate sequences of the HIV genomes present in the actual samples. Importantly, the sequences thus generated are used as candidates for the proteomic analysis, and thus if the proteomics and the genomic sequences match we may say that we have a putatively translated novel sequence. Finally, we show in Figure 4 that our pipeline identifies a novel isoform of the Env protein, which is known to be hypermutated to evade the immune response. Thus, our pipeline does indeed match proteins which are expected to be highly mutated, and expected to exist in the sample, thus validating the proteogenomics approach. Finally, a single novel micropeptide was also found, as shown in Figure 5.

As in the HepG2 experiment above, the proteogenomics pipeline captures a substantial number of proteins, showing that the proteogenomics pipeline successfully recapitulates the standard proteome along with the novel sORF proteome: at the filtering

thresholds described in Methods, for the HIV-1(MN)/H9 CL.4 virus, 1606 proteins were found, reduced to 1319 after clustering, of which 1 mapped to a novel sORF; for the HIV-1(MN)CL.4/CEMx174(T1), 1775 proteins were found, reduced to 1457 after clustering, of which 4 mapped to novel sORFs; for the HIV-1 ADA/SUPT1-CCR5 CL.30, 1420 proteins were found, reduced to 1105 after clustering, of which 7 mapped to novel sORFs. All but one of these were eliminated by the BLAST search filtering. The complete results are shown in Table 4.

Thus, in this chapter we have shown that, by our 2D LC-MS/MS platform, along with a bioinformatic approach to generating databases which include micropeptides generated by short open reading frames, by directly translating *in silico* all open reading frames shorter 100 codons and longer than 5 codons in assembled transcriptomes. We utilize this system to find evidence of translation of two novel micropeptides expressed in the HepG2 cell line, and one novel micropeptide in a purified HIV-1 strain.

Figure 1b. Gaussian fit and raw distribution for PeptideProphet for Mascot results, for hits with charge state +2

Figure 2a. Micropeptide hit in gene SLC35A3. Fragmentation table shows good coverage of both B and Y ions. Mass spectrum shows one set of unidentified peaks which are likely due to incomplete fragmentation of doubly charged precursor.

Figure 2b. Micropeptide sequence maps to the gene Solute carrier family 35 member A3 (ENST00000370153.6), whose function is a UDP-GlcNAc transporter in the Golgi apparatus. The transcript is 5708 nt long, with a ~1100 nucleotide CDS and a long (~4500 nucleotide) 3'UTR. The 12-codon ORF is in the 3'UTR at positions 5410-5448 with an in-frame stop, and alternative start leucine codon which is recoded as NUG to Methionine, for a final translation of MSVCCFICNYKII. The peptide is detected only in the membrane fractions.

Figure 4. Novel gp120 isoform in Strain HIV-1_{ADA-M}. The ORF discovered maps to within the normal Env gene. The protein is hypermuted and so does not map normally when searched with a standard database of proteins. Discovery of novel Env isoforms is to be expected due to HIV biology, and thus shows that the proteogenomics method used here is Shows that de novo assembly finds viral sequence variants. Alignment of novel sequence with canonical HIV Env isoform done by Jaligner with standard settings.

Figure 5a. Micropeptide Hit in Strain HIV-1_{MN} from HIV-1(MN)CL.4/CEMx174(T1). Spectrum was acquired a total of 9 times across replicate injections, at an average elute time of 6786 seconds, with 6.8 standard deviation. The peptide acquired covers the complete open reading frame. Shown here is an example spectrum with corresponding mass table.

Figure 5b. All spectra acquired from novel HIV-1 micropeptide.

Table 2. All proteins identified in HepG2 by this analysis. Database searching was performed on the datasets described in Table 1. In column 1, protein identifications are shown along with their cluster partners. In column 2, identification probabilities are shown. In column 3, spectral counts are shown for each protein identification. Probabilities here were calculated by the PeptideProphet algorithm and by the ProteinProphet algorithm, and the protein probabilities are displayed.

Chapter 4: Micropeptidomics of Mouse CNS by ribosome profiling and mass spectrometry

Introduction

Neuropeptides are small signaling molecules in the CNS of many species, and play important roles in the regulation of behavior and many other physiological processes (Burbach, 2011; Nathoo, Moeller, Westlund, & Hart, 2001; L. S. Nelson, Rosoff, & Li, 1998; Zhang, Buchberger, Muthuvel, & Li, 2015). In the past two decades, many novel neuropeptides have been discovered by untargeted approaches (Hori et al., 2001; Kojima et al., 1999; Meunier et al., 1995; Sakurai, Amemiya, Ishii, Matsuzaki, Chemelli, Tanaka, Williams, Richardson, et al., 1998; Tatemoto et al., 1998). Some of these novel neuropeptides and their receptors, in particular nociceptin and orexin A and B, have since gone on to clinical trials as drugs or drug targets (Coleman & Renger, 2010; Lambert, 2008), which have recently produced the drug suvorexant (Patel, Aspesi, & Evoy, 2015). Thus, the discovery of novel neuropeptides may allow novel approaches to pharmacologic intervention in psychiatric disorders. However, in the past decade, no novel neuropeptides have been discovered, and new approaches to novel neuropeptide discovery may be needed.

A recently developed technique for studying translational regulation, ribosomal profiling, has uncovered that there may be many short, unannotated open reading frames (sORFs) in mammalian genomes (Brar & Weissman, 2015; Ingolia, 2014; Ingolia et al., 2014; Kondo et al., 2010; Slavoff, Heo, Budnik, Hanakahi, & Saghatelian, 2014). The translated products of these sORFs are very short peptides (<100 amino acids), and have been named micropeptides. Several of these have been found to be functional in human tissue systems such as skeletal muscle and the cardiovascular system (Anderson et al., 2015; C. Lee et al., 2015; Magny et al., 2013). In particular, the Toddler peptide has been found to be a secreted ligand for a G-protein coupled receptor (GPCR) (Pauli et al., 2014). Since nearly all known neuropeptides are ligands for GPCRs (Burbach, 2011;

Zhang, Wang, Parks, & Civelli, 2011), these recent discoveries motivate the hypothesis that some of these sORF-encoded peptides could be undiscovered neuropeptides.

In Chapters 2 and 3, I have developed and applied a novel method for profiling cell and tissue samples for micropeptides by mass spectrometry(Tharakan, Tao, Ubaida-Mohien, Dinglasan, & Graham, 2015). This micropeptidomics method can be easily adapted to the CNS to perform neuropeptidomics(Romanova & Sweedler, 2015), which is an approach that entails extraction of all neuropeptides from brain cells or brain tissue samples and then sequencing all neuropeptides by mass spectrometry. The method I have developed can increase neuropeptide discovery rates by several fold over traditional mass spectrometry-based neuropeptidomics techniques(Tharakan et al., 2015). Therefore, a combination of my neuropeptidomics method with ribosomal profiling of mouse brain allows novel sORF-encoded neuropeptide discovery in the mammalian CNS.

In this Chapter, we apply the same micropeptidomics methods to the mouse brain, in an attempt to apply the methods to a more constrained system and gain biological insights. While biochemical detection of these micropeptides proves that the micropeptides are translated, but this does not necessarily mean that they are functional, as they may be translational byproducts. We hypothesized in this Chapter that micropeptides which are functional in the brain will be expressed in a regulated manner during adolescent development. Thus, in order to validate the micropeptide targets thus discovered, we quantified these micropeptides by mass spectrometry, by time and mass tag quantitative profiling. Thus, the goals of this Chapter are, first, the discovery of translated micropeptides in the mammalian brain; with the hypothesis that the mammalian brain will have functional micropeptides. We approach this hypothesis by discovering sORFs that have ribosomal content in mouse brain by ribosomal profiling

(RP) and by mass spectrometry-based neuropeptidomics, using RP-derived sequences as databases for MS analysis. Second, we validate the novel CNS micropeptides by examining their regulation in development, with the hypothesis that micropeptides which are functional in the mammalian brain will change their abundance over the course of development. We approach this hypothesis by performing a screen for regulated micropeptides over the course of adolescence.

Methods

Mouse brain peptide extraction. A protease inhibitor solution was prepared by dissolving 1 Sigma Protease Inhibitor Tablet in 50 mL of Phosphate-buffered Saline, for a final concentration of AEBSF, 2 mM, Aprotinin, 0.3 μ M, Bestatin, 130 μ M, EDTA, 1 mM, E-64, 14 μ M, and Leupeptin, 1 μ M. This buffer was then used to perfuse the animals according to standard protocols after deep anesthetization, with perfusion being accomplished at a rate of 4 mL per minute for 5 minutes, until liver was visibly cleared of blood. Whole brains were then dissected out by standard protocols, and brains were heat inactivated by the Denator laser-guided heat inactivation system according to published protocols (Svensson et al., 2009), in the procedure for fresh frozen tissue without tissue structure preservation. The brains were then flash-frozen on liquid nitrogen and stored at -80C. Brains were then immersed into cold .5% acetic acid (pH ~2) to thaw, with 7.5 μ L/mg tissue, minced, and triturated with a 21G needle, then transferred to a 5 mL Duall tissue grinder, to be homogenized with 20 strokes left and right. To shear DNA to reduce viscosity, samples were then treated with sonication with a 10 second burst at level 4, with a 20 second pause on ice, for 5 cycles. The homogenates were then cleared by centrifuging at 20,000xg at 4C for 20 minutes. The supernatant was then collected and loaded onto 30 kDa molecular weight cutoff filters, and centrifuged through them to

remove high molecular weight components, by centrifugation at 14,000xg for 10 minutes, at room temperature so as not to disrupt the chemistry of the filter. Flowthrough of the filtration was then collected and desalted by solid-phase extraction. Briefly, C18 SepPaks (Waters) were preconditioned with 10 mL of a buffer of 5% acetonitrile, 94.9% water, with .1% formic acid. The flowthrough sample was then loaded on these columns. Flowthrough of the filtration was then loaded onto the column. The sample was then desalted by washing with 20 mL of the preconditioning buffer, then eluted with a buffer of 70% acetonitrile, 29.9% water, with .1% formic acid. This elution was then evaporated to dryness under vacuum.

Database construction from ribosome profiling data. Ribosome profiling data was obtained from two published datasets, a cerebellum ribosome profiling dataset(Ishimura et al., 2014) and a frontal lobe ribosome profiling dataset(Hornstein et al., 2016). Briefly, in the former dataset, three cerebella were pooled for each library preparation, with brain tissues homogenized in a polysome buffer with DNase I, 100 ug/ml cycloheximide, and 2 ug/ml harringtonine, blocking both ribosome elongation and ribosome initiation(Ingolia et al., 2011). Samples were treated with RNase I and pelleted into a 1M sucrose cushion, as previously described(Ingolia, Brar, Rouskin, McGeachy, & Weissman, 2012). Upon gel purification, 26-34 nucleotide length fragments were purified, and library preparation proceeded according to standard protocols. In the latter dataset, the frontal lobe of the mice was dissected by standard protocols, and the ribosome footprints were isolated and purified in the standard manner. However, the ligation step was then omitted and a small RNA library preparation kit was used to produce the final library (smRNA-Seq Kit for Illumina). Finally, a ribosome profiling dataset was generated from mouse brain using published protocols(Ingolia et al., 2012). From these sequencing data, proteome

databases were constructed using a novel method by Olexiouk (Olexiouk, Menschaert, et al, forthcoming).

Mass spectrometry-based peptidomics analysis and TMT labelling, database searching and publication re-analysis. Datasets used for this study were the peptidomics study generated above, and the Sharma et al. mouse brain proteome (Sharma et al., 2015). In that study, brain regions were dissected from coronal sections from P60 mice. We used datasets only from the pre-frontal cortex experiments, and microglial and neuronal primary cell cultures. From this, the database searching was performed as in Chapter 3, with the ribosome profiling-based datasets concatenated as described and searched with the previously described settings.

Results

In these experiments, we performed peptidomics and proteogenomics analyses on the mouse brain in order to discover novel neuropeptides. In one experiment, we extracted neuropeptides from 6 mouse brains, one from each of three adolescent timepoints, at 4 weeks, 5 weeks and 6 weeks old, with two replicates per timepoint. The samples were labelled with TMT and for quantification. This experiment produced a dataset, at 1% FDR, of 368 proteins in 311 clusters, with the highest abundant protein being Immunoglobulin at 651 spectra followed by Ubiquitin at 617 spectra (Table 1). This is to be expected for a neuropeptides extraction, which extracts only soluble proteins. Of the 601 clustered proteins, 15 were known neuropeptides or their precursors (Table 2). We note that this workflow cannot differentiate between neuropeptides and their precursors, since a tryptic digest was done. The substantial number of neuropeptides

detected shows that the protocol is sensitive enough to observe neuropeptides, which are generally thought to be low abundance as signaling molecules.

Sixteen spectra mapped to the transcript 2210013O21Rik, which is a transcript without an annotated function. The peptide sequence thus determined maps to exon 1 of the corresponding transcript, with a canonical start and stop codon, defining a short ORF. This sORF contains 5 tryptic cleavage sites, producing 6 tryptic peptides, or 5 if one proline-blocked tryptic site is ignored(Olsen, Ong, & Mann, 2004). Of these, 3 tryptic peptides were detected by mass spectrometry, with high probabilities for all peptides (Table 3). An example spectrum and mass table from the peptide is shown in Figure 1. We also examined the translation of the protein by ribosome profiling. All three mouse brain ribosome profiling datasets showed substantial coverage of this locus by ribosome profiling reads (Figure 2).

To further examine the expression of this peptide, we also attempted to study its regulation over the course of adolescent development. We utilized the TMT labelling data to look for quantitative changes in the expression of the peptide over the course of adolescence, from 4 weeks development, 5 weeks development, and 6 weeks development. However, no substantial change was found in the abundance of the peptide over this timecourse (Figure 3). It is possible that, since whole brains were used in this experiment, there may be more region-specific changes which could not be found. Unlike embryonic development, the mouse brain undergoes only subtle changes during the course of adolescent development, although specific regions may change more substantially.

To further examine this peptide and its function, we searched for the expression of the underlying transcript in the database BioGPS, which has microarray-based datasets detailing expression of all known transcripts. These results are summarized in

Figure 4. The transcript is found to have highest expression in mouse brain out of all tissues in mouse, in particular in dorsal root ganglia, hypothalamus, and amygdala. The latter two regions are involved in regulation of behavior, indicating that this peptide is likely to be a behavior regulating neuropeptide.

In order to rule out contamination from the periphery in our sample, we re-analyzed datasets from Sharma et al (see Methods), using proteomics data from cultured primary neurons and microglia. These datasets also contained the novel peptide, albeit at a lower intensity, likely because they were not targeted toward soluble peptide extractions. Thus, our bioinformatics framework allows us to find a novel micropeptide in published datasets, as well. Since these proteomics datasets were derived from cultured primary neurons and microglia, we can conclude that the peptide is produced locally, rather than crossing from the periphery as a secreted hormone.

Finally, we further utilized this published dataset to attempt to find brain region-specific micropeptides. We used published datasets from dissected pre-frontal cortex, a region known to undergo changes during adolescence. While these datasets were derived from P60 mice, which are adult mice, the targets thus derived may be interesting candidates for future work on adolescent development, since they are expressed in the pre-frontal cortex. Analyzing these datasets using the cerebellum-derived database generated a dataset of 7,309 proteins in 5,312 clusters. Of these, 61 were potential micropeptide hits. These were subjected to the screening by BLAST searches as described in Chapter 3. Twelve micropeptides were found to be translated from 5' untranslated regions of known transcripts. Of these, 11 were found to map ambiguously to another isoform of a known gene, leaving one putative micropeptide. Twenty-six micropeptides were found to be translated from annotated long non-coding RNAs. Of these, homology screening rules out all but one. Thirteen micropeptides were found to

be alternately encoded from known exons. As we argued in Chapter 1, these cannot be unambiguously identified from mass spectrometry data. Ten micropeptides were found to be translated from transcripts expected to be degraded by nonsense-mediated decay; of these, one survived homology screening.

Discussion

In this chapter, we have developed a new proteogenomics framework utilizing ribosome profiling data, rather than RNAseq data, for generating databases for proteogenomics analyses. While no direct comparison between the two methods is within the scope of the work here, we suggest that this method appears to be more effective, since the search space is decreased by considering only ORFs which have substantial ribosomal content. As discussed in the introduction to this thesis, the ribosome profiling data should, in theory, match almost exactly to the proteomics data. However, it has been widely observed that ribosome profiling data and proteomics data mismatch to a large extent. Thus, allowing the two techniques to complement each other by orthogonally confirming results is a proteogenomics technique that allows the search space of the analysis to be decreased while nevertheless allowing dual confirmation of the novel protein identifications. Thus, in the case of searching the mouse brain for novel proteins, the ribosome profiling-based proteogenomics technique was successful, discovering indeed a new peptide.

Short open reading frames (sORFs) are sequences of nucleotides in the human genome containing a start and an in-frame stop codon separated by less than 300 nucleotides(Andrews & Rothnagel, 2014). The gene products of these sORFs are necessarily very short proteins of less than 100 amino acids. While there are many more

sORFs in most genomes than there are known genes [for example, the mouse genome has ~25,000 known genes, but ~47 million sORFs(Brown & Hancock, 2006; Crappe et al., 2013)], these very short genes have historically been understudied in all species, because of common bioinformatic, biochemical and genetic assumptions. First, since peptides generated from these sORFs would be very short, it was thought that they were unlikely to fold into stable structures which would allow them to be functional(Ingolia et al., 2014). Second, it is difficult to detect evolutionary conservation of these ORFs(Couso, 2015), and in classical random mutagenesis experiments, a shorter gene is less likely to be 'hit' than a longer one, leading to few phenotypes from these genes(Basrai et al., 1997). Finally, in a randomly-generated genome, there is a very high rate of occurrence of ORFs of <100 amino acids by random chance(Frith et al., 2006). All these lines of thinking led to the assumption that sORFs were non-functional, an assumption which has turned out to be wrong.

The assumption has been disproven in the following ways. First, it has recently been recognized that intrinsically disordered proteins have many biological functions(Dyson & Wright, 2005; Wright & Dyson, 2015). Second, if homology detection is adjusted for the small length of these genes, a great deal of conservation can be found(Bazzini et al., 2014; Mackowiak et al., 2015). Finally and most importantly, next generation sequencing techniques such as RNA sequencing and ribosome profiling have shown that many of these sORFs are both transcribed and translated(Ingolia et al., 2014; Ingolia et al., 2011). In particular, several significant novel genes, with likely roles in human disease, have been found recently. The peptide Myoregulin, which regulates the sarco/endoplasmic reticulum calcium ATPase (SERCA) pump in human skeletal muscle, was recently found by a bioinformatic screen(Anderson et al., 2015). This peptide is a fundamental discovery for the understanding of skeletal muscle physiology.

Similarly, the peptides MOTS-c (mitochondrial open reading frame of the 12S rRNA-c), discovered bioinformatically (C. Lee et al., 2015), and Toddler, discovered by ribosome profiling (Pauli et al., 2014), are involved in regulation of insulin metabolism in mouse and cardiovascular regulation in human, respectively (Yang, Maguire, & Davenport, 2015).

Neuropeptides have long been recognized to be involved in regulation of behavior of human and other species (Burbach, 2011; Nathoo et al., 2001; L. S. Nelson et al., 1998; Zhang et al., 2015), and their involvement has been suggested in mental illness as well (Bissette et al., 1986; Caceda, Kinkead, & Nemeroff, 2007). In recent decades, the discovery, by various biochemical approaches, of novel neuropeptides has provided insights into the molecular regulation of behavior (Civelli et al., 2013; Hori et al., 2001; Kojima et al., 1999; Meunier et al., 1995; Sakurai, Amemiya, Ishii, Matsuzaki, Chemelli, Tanaka, Williams, Richardson, et al., 1998; Tatemoto et al., 1998). For example, discovery of the orexin system, the peptides orexin A and orexin B and orexin receptor 1 and 2, has increased our understanding of sleep homeostasis, as well as pain and fear expression (de Lecea & Sutcliffe, 1999; Flores, Saravia, Maldonado, & Berrendero, 2015; Nunez, Rodrigo-Angulo, Andres, & Garzon, 2009). In this way, discovery of novel neuropeptides may provide insights into mental illness, for example, in the dysregulation of emotional expression. Furthermore, these discoveries have also yielded productive drug targets (Patel et al., 2015). Indeed, neuropeptides almost entirely signal through G-protein coupled receptors (GPCRs), which are the class of cell-surface molecules most commonly targeted by existing drugs (Civelli et al., 2013). Thus, discovery of novel neuropeptides is likely to produce new modes of pharmacological intervention in psychiatry. By discovering and validating novel sORF encoded peptides in the mammalian brain, novel neuronal signaling systems can be discovered; and by

studying these novel genes in the context of schizophrenia novel approaches for intervention in psychiatry can be produced.

In this chapter, we have implemented a novel method for discovery of neuropeptides, which can easily be applied to any biological system. Here, we apply this system to the mouse brain. Here we combine novel neuropeptidomics techniques by mass spectrometry-based peptidomics with novel bioinformatics methods to discover micropeptides. Neuropeptidomics by mass spectrometry has been performed for many years, and standard techniques that have developed have been solubilization of brain extracts into acetic acid as a preservative against neuropeptide degradation. The novel neuropeptidomics methods we incorporate here are the heat-inactivation of brain samples by laser-guided heat delivery to the sample to a specific temperature for a specific time, immediately after dissection of the brain, in order to block neuropeptidases whose targets are unknown; simultaneously, we use microfiltration techniques, based on the highly successful FASP protocols, to purify the neuropeptides after heat-inactivation, preservation by acid, and extraction. We also combine these methods with novel techniques developed to discover micropeptides from mass spectrometry data. These techniques utilize ribosome profiling data with statistical methods to generate lists of all potentially translated ORFs in a transcriptome. By applying trypsin digestion to the neuropeptidomics extracts described above, we can use the databases thus generated to find micropeptides which act as neuropeptides, which is to say, secreted signaling molecules. As a proof of concept, in this chapter we describe a novel peptide translated from a short ORF, which is abundantly detected in our neuropeptidomics extracts. While we detect many cytosolic proteins which are not neuropeptides in our mass spectrometry data, and therefore cannot say with certainty that our novel peptide is a neuropeptide, the enrichment of such a peptide in the hypothalamus and amygdala

suggests that it may be involved in behavioral regulation, and a publication in peripheral T cells shows that activation by the peptide can occur by treatment in cell culture media, suggesting that it acts as a signaling peptide. Thus, we can show that our platform is indeed able to find novel micropeptides, and we have a strong suggestion that the peptide we discovered is a novel neuropeptide. We suggest, therefore, that our platform can find novel neuropeptides, and constitute a significant contribution to the field of neuropsychiatry.

Figure 1. Micropeptide hit in mouse brain from peptidomics experiment. Transcript name is 2210013O21Rik. The protein produces 16 total spectra, and has 65% coverage. An example spectrum is shown.

Figure 2. Ribosome profiling data showing translation of novel sORF. Bottom, genomic locus and transcript structure of sORF transcript. Four transcript isoforms of varying length and exon structure can be seen, but all four have a single ORF within the first exon. Above, an alternative transcript on the opposite genomic strand is shown in green. Above, overall exon structure of transcript. Above, ribosome profiling reads mapping to sORF from frontal lobe data (see Methods). Above, ribosome profiling reads mapping to sORF from cerebellum data (see Methods). Above, ribosome profiling reads mapping to sORF from whole brain ribosome profiling data.

Figure 3. TMT labeling experiment for timecourse quantitation over mouse adolescence. Sample labels for each panel from left to right: 2 mice, 4 weeks old, 2 mice, 5 weeks old, 2 mice 6 weeks old. Panels from left to right: 14-3-3 scaffold protein, the TRH peptide hormone, the novel sORF found in this study, and the enkephalin protein. No clear differences in any protein. Each timecourse is for one representative tryptic peptide.

Figure 4. Analysis of novel sORF through BioGPS transcript expression data. Expression levels are organized into peripheral tissues, immune cells, osteoblasts, cell lines, eye tissue, and brain regions. Expression is highest in cell lines, specifically the NIH 3T3 line. However, among tissues expression is highest in brain, specifically in the dorsal root ganglion, hypothalamus, and amygdala.

Ravi Tharakan Curriculum Vitae

Home Address: 3925 Beech Ave #415, Baltimore, MD 21211

Office Address: Meyer 4-157, 600 N. Wolfe Street, Baltimore, MD 21205

Date of Birth: 1/1/1984, Arlington, VA

EDUCATION

JOHNS HOPKINS UNIVERSITY

Baltimore, MD

PhD, Cellular and Molecular Medicine

May 2017

- Dissertation supervised by Dr. Akira Sawa, Department of Psychiatry
- Focus: Proteogenomics Approaches to Micropeptide Discovery

WESTERN MICHIGAN UNIVERSITY

Kalamazoo, MI

Master of Arts, Philosophy

May 2011

- GPA: 3.95

JOHNS HOPKINS UNIVERSITY

Baltimore, MD

Bachelor of Arts, Philosophy

May 2007

- GPA in major: 3.81/4.0

Bachelor of Sciences, Biomedical Engineering

May 2007

- Concentration: Computer Science

RESEARCH EXPERIENCE

JOHNS HOPKINS MEDICAL INSTITUTIONS

Baltimore, MD

PhD Candidate, Sawa Lab, Psychiatry, *March 2015-Present*

- Discovery of sORF-encoded micropeptides by proteomics and ribosome profiling.

PhD Candidate, Graham Lab, Molecular and Comparative Pathobiology, *May 2012-March 2015*

- Peptidomic, metabolomic and lipidomic profiling of innate immune response to acute HIV infection in an SIV macaque model.

Rotation Student, Huganir Lab, Neuroscience, *March 2012-May 2012*

- Interactome of C-terminal 3Y peptide of AMPA receptor.

Rotation Student, Sawa Lab, Psychiatry, *Jan 2012-March 2012*

- Direct conversion of adult human fibroblasts to neurons.

Rotation Student, Zink Lab, Molecular and Comparative Pathobiology, *Sept 2012-Dec 2012*

- Mechanism of immunomodulation of minocycline by lipid raft localization in T cell lines.

Bioinformatician, Johns Hopkins NHLBI Proteomics Center, *May 2007-September 2009*

- Data analysis of mass spectrometric proteomics data.

PROFESSIONAL ACTIVITY AND AWARDS:

Honors:

- **Young Investigator's Award**, 12th Annual International Society for Neurovirology Symposium, Nov 2nd, 2013.
- **AAAS/Science Program for Excellence in Science**, 2013-15. Sponsored by Dr. Rajini Rao.
- **Abstract Invitation**, Keystone Symposia, "HIV Pathogenesis – Virus vs. Host," 2014.

Reviewer:

- Invited by Editor Joshua Sheetz, *Yale Journal of Biology and Medicine*, 2017.
- Invited by Editor Royston Goodacre, *Metabolomics*, 2016.
- *Ad hoc* peer review for 6 manuscripts with David Graham, *Proteomics*.
- Invited by Editor Lennart Martens, *Proteomics*, 2009.
- *Ad hoc* peer review with David Graham, Wellcome Trust Grant Application, 2008.

Selected Presentations:

- Oral Presentation: "Discovering Novel Neuropeptide Genes in the Human Genome." Cellular and Molecular Medicine Program Retreat, Baltimore, MD, Sept 15th, 2016.
- Poster Presentation: "Proteomics of HIV-1 Viral Isoforms: Studying Viral Protein Evolution by Mass Spectrometry." 62nd Annual American Society for Mass Spectrometry, Baltimore, MD, June 14th-19th, 2014.

- Poster Presentation: “Multiomic Profiling of Peripheral Immune Response in an SIV Macaque Model of HIV-Associated Neurological Disease.” 12th Annual International Society for Neurovirology, Washington, DC, Oct 12th–Nov 2nd, 2013.
- Poster Presentation: Cellular and Molecular Medicine Program Retreat, Baltimore, MD, Sept 12th, 2013.
- Oral Presentation: “Investigating Minocycline’s Mechanism of Immunomodulation.” Cellular and Molecular Medicine Program Rotation Presentations, Baltimore, MD, Dec 9th, 2011.
- Poster Presentation: “When every spectrum counts: An integrated grid and cloud enabled software pipeline for identification of elusive proteins.” 59th Annual American Society for Mass Spectrometry, Denver, CO, June 5th-9th 2011.
- Oral Presentation: Van Eyk Lab Retreat, “Redundancy Removal by Homology Graph Clustering.” Baltimore, MD, May 9, 2008.

Professional Activity:

- Attended Conference: 63rd Annual American Society for Mass Spectrometry, St. Louis, MO, June 1st-5th, 2015.
- Attended Course: “Case Studies in Quantitative Proteome Bioinformatics,” American Society for Mass Spectrometry, St. Louis, MO, May 29th-30th, 2015.
- Attended Course: “Stable and Transient Protein-Protein Interactions: Discovery, Quantification and Validation,” American Society for Mass Spectrometry, St. Louis, MO, June 14th-15th, 2014.
- Attended Training Course: Society of Nuclear Medicine, In Vivo Preclinical Imaging: Introductory Workshop. Johns Hopkins University, March 20-21, 2012.
- **Co-organizer (Submissions and Program Coordinator)**, 4th Annual Western Michigan Graduate Philosophy Conference, Kalamazoo, MI, Dec 3rd-5th 2010.
- Attended Conference: 3rd Conference on Integrated History and Philosophy of Science, Indiana University, Bloomington, IN, Sept 23rd-26th, 2010.
- **Visiting Scientist:** Institute for Genomics and Bioinformatics of the Technical University of Graz, Graz, Austria, March-August 2009.
- Attended Course: “Proteomics Informatics,” Institute for Systems Biology, Seattle, WA, Nov 1st-8th, 2008.

Teaching Experience:

- **Instructor**, Biomedical Ethics; designed and taught course: Western Michigan University, Spring Semester, 2010.
- **Instructor**, Critical Reasoning (Introductory Logic Course); designed and taught course: Western Michigan University, Summer Sessions 1 and 2, Fall Semester, 2010.
- **Teaching Assistant**, Introduction to Ethics, Spring Semester 2010, and Critical Reasoning (Introductory Logic Course), Western Michigan University, Fall Semester 2010.
